Abstract

Exchange-bias has been reported in bulk nanocrystalline Fe_2MnAl , but individual thin films of this Heusler alloy have never been studied so far. Here we study the structural and magnetic properties of nanocrystalline thin films of $\text{Fe}_{2-x}\text{Mn}_{1+x}\text{Al}$ ($x = -0.25, 0, 0.25$) obtained by sputtering and *ex-situ* post-deposition annealing. We find that Fe_2MnAl films display exchange-bias, and that varying Mn concentration determines the magnitude of the effect, which can be either enhanced (in $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$) or suppressed (in $\text{Fe}_{2.25}\text{Mn}_{0.75}\text{Al}$). X-ray diffraction shows that our films present a mixed $L2_1$ - $B2$ Heusler structure where increasing Mn concentration favors the partial transformation of the $L2_1$ phase into the $B2$ phase. Scanning transmission electron microscopy (STEM) and energy dispersive X-ray spectroscopy (EDX) reveal that this composition-driven $L2_1 \rightarrow B2$ transformation is accompanied by phase segregation at the nanoscale. As a result, the $\text{Fe}_{2-x}\text{Mn}_{1+x}\text{Al}$ films that show exchange-bias ($x = 0, 0.25$) are heterogeneous, with nanograins of an Fe-rich phase embedded in a Mn-rich matrix (a non-negative matrix factorisation algorithm was used to give an indication of the phase composition from EDX data). Our comparative analysis of XRD, magnetometry and X-ray magnetic circular dichroism (XMCD), shows that Fe-rich nanograins and Mn-rich matrix are composed of a ferromagnetic $L2_1$ phase and an antiferromagnetic $B2$ phase, respectively, thus revealing that exchange-coupling between

these two phases is the cause of the exchange-bias effect. Our work should inspire the development of single-layer, environmentally-friendly spin valve devices based on nanocomposite Heusler films.

Introduction

For a sustainable economy, the development of environmentally-friendly magnetic applications is a priority^{1,2}. In this field, magnetic materials for energy applications (i.e. permanent magnets and magnetocalorics) have insofar been at the forefront, with focus on reducing cost by replacing rare with abundant elements^{3,4}, and on exploring simpler and greener device designs⁵. However, the same criteria can be extended to other applications.

Magnetic field sensors based on the spin-valve device concept require a multilayer stack comprising two soft ferromagnetic layers (FM) and an antiferromagnetic (AFM) layer (usually IrMn). The magnetization of the outer FM layer is free to rotate in response to external magnetic fields, while the magnetization of the inner FM layer is pinned to the underlying AFM layer *via* the exchange-bias effect⁶. A simpler, cost-effective device could be obtained if the multilayer stack were replaced by a single layer of material with exchange-bias. For optimum sustainability, this single layer should contain neither Ir (one of the scarcest elements in earth's crust) nor any other scarce or hazardous material⁷.

Exchange-bias has long been known in heterogeneous granular systems that present the necessary coexistence of AFM and FM phases at the nanoscale⁸. These systems have been shown to work at room temperature⁹ and have been proposed for spintronics applications. Suitable morphologies comprise: i) core-shell nanoparticles obtained by mechanical milling¹⁰, thermal decomposition¹¹ and different chemical routes^{12–14}; ii) magnetic nanoparticles embedded in AFM matrices obtained by cluster beam deposition^{15–17}, selective reduction¹⁸ and co-sputtering¹⁹; iii) phase segregated alloys obtained by mechanical²⁰ and thermal^{21–23} treatments.

Moreover, exchange-bias has been reported in alloys with nominally homogeneous composition, where the separation between FM and AFM phases can be intrinsically established by structural phase transformations²⁴ and/or chemical disorder^{25,26}. These conditions occur in Mn-based Heusler alloys that present the shape memory effect^{27–35}, compensated ferrimagnetism³⁶ and spin glass behaviour^{21,37,38}. The observation of exchange-

bias in nominally single Heusler alloys is intriguing for spintronic devices because of their highly spin-polarized conduction band^{39–42}.

The Heusler alloy Fe_2MnAl is promising for environmentally-friendly spin valve devices because it is ferromagnetic at room temperature^{43,44}, it is made of abundant non-hazardous materials and can be prepared as core/shell nanoparticles that display exchange-bias⁴⁵. However, Fe_2MnAl has not been studied in the form of individual thin films to date.

Here, we report on the structural and magnetic properties of nanocrystalline thin films of $\text{Fe}_{2-x}\text{Mn}_{1+x}\text{Al}$ ($x = -0.25, 0, 0.25$) obtained by sputtering and *ex-situ* post-deposition annealing. We show that our films display a mixed $L2_1$ - $B2$ Heusler structure in which substitution of Mn for Fe progressively drives the $L2_1 \rightarrow B2$ phase transformation. Macroscopic magnetic measurements reveal that this transformation favours exchange-bias, but depresses magnetization. A detailed STEM investigation shows that these crystallographic and magnetic changes are the result of a nanosegregation process, which ultimately leads to an heterogeneous microstructure in which coarsened crystal grains of an Fe-rich phase are embedded in a Mn-rich phase. We use a non-negative matrix factorisation (NMF) algorithm^{46,47} to give an indication of the composition of the two phases. Moreover, we clarify the magnetic nature of the phases via a quantitative comparison between macroscopic and microscopic magnetic measurements of the $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ film. XMCD measurements yield an overall magnetic moment which exceeds, by a factor two, the value obtained from the (macroscopic) saturation magnetization calculated over the whole volume of the film, measured by SQUID. However, we find good agreement if we use the volume of the Fe-rich phase as determined from the STEM images, such that we are able to identify the Fe-rich phase as the $L2_1$ ferromagnetic phase and the Mn-rich phase as the antiferromagnetic $B2$ phase. In this heterogeneous $L2_1$ - $B2$ mixed state, the exchange-bias results from the exchange-coupling between phase-separated ferromagnetic and antiferromagnetic regions. Our environmentally-friendly nanocomposite Heusler films should be of interest for single-layer spin valve devices which are sustainable.

Experiment

$\text{Fe}_{2-x}\text{Mn}_{1+x}\text{Al}$ films ($x = -0.25, 0, 0.25$) with a thickness of 200 nm and 2.5 nm-thick Al capping layers were grown by multi-target DC-magnetron sputtering on thermally-oxidized Si substrates. After reaching a base pressure of 1×10^{-7} Pa in the deposition system, films and capping layers were deposited at a rate of 0.06 nm s^{-1} and 0.017 nm s^{-1} respectively

(in a 99.999% Ar atmosphere with pressure 1.37 Pa). The power supplied to each of the (elemental) magnetron targets was carefully controlled in order to control the individual deposition rates, and hence the film composition. The samples were subsequently *ex-situ* annealed at 300 °C for 9 hrs in a vacuum of 1×10^{-6} Pa to induce structural ordering.

After annealing, the nominal compositions (calculated from the deposition rates of the individual elements) were confirmed by Energy Dispersive X-ray analysis (EDX) using a Camscan MX2600 FEG-SEM. To rule out any possible artefacts arising from the interaction of the electron beam with the substrate in these 200 nm-thick films, subsequently used for the magnetic studies, compositions were also confirmed in 600 nm-thick twin samples that were specifically grown for this purpose.

The surface morphology of the films was studied by tapping mode Atomic Force Microscopy (AFM) (Bruker, MM8 with a Nanoscope V controller). We used TAP300AL Budget Sensors cantilevers and we analysed the images using the Gwyddion software package⁴⁸.

Structural characterisation was carried out by X-ray diffraction (XRD) using a Bruker D8 Advance diffractometer. To eliminate the substrate peaks we used an off-coupled $\theta/2\theta$ scan with an 8° θ offset, which did not affect the intensity of the diffraction peaks, given that our films were untextured. The experimental peak intensities were determined by profile fitting using HighScore+ software. The theoretical intensities corresponding to the fully ordered crystals that we have used for our quantitative analysis (Fig.1) were calculated using the VESTA⁴⁹ software package.

Film morphology and elemental spatial distribution were analysed with a FEI Osiris Scanning Transmission Electron Microscope (STEM) operated at 200 kV. The microscope was equipped with a high brightness electron gun and a large area EDX detector (Bruker Super-X, 0.9 sr solid angle for collection). Images were acquired in STEM-HAADF (High Angle Annular Dark Field) mode, in which the brightness depends upon the local thickness and average atomic number. For STEM studies, $\text{Fe}_{2-x}\text{Mn}_{1+x}\text{Al}$ ($x = -0.25, 0, 0.25$) films with 50 nm thickness and 2.5 nm Al capping layers were deposited and *ex-situ* annealed (under the same conditions as above) on commercial TEM sample supports made of 200 nm-thick SiN membranes on 200 μm -thick Si chips with a $0.1 \times 0.1 \text{ mm}^2$ window. The EDX data was analyzed using a NMF (Non-negative Matrix Factorisation) algorithm³² run inside

Hyperspy⁵⁰, an open-source python-based toolkit for the analysis of electron microscopy data. The NMF algorithm improves the signal-to-noise ratio (SNR) and enables correlations between the spatial distribution of elements to be identified. Such correlations emerge from statistical analysis and consist of maps that describe the distribution of chemical compounds rather than just elements. The algorithm can be thought of as a generalised fitting routine in which a set of EDX spectra are modelled into a linear combination of different factors (which can be both single elements and chemical compounds), weighted by a set of corresponding loadings. The loading for each pixel represents the weight in the linear combination that reconstructs the original dataset and thus indicates the presence of a given component (and therefore the associated compound) in that pixel.

All the magnetic measurements were carried out on the 200 nm-thick $\text{Fe}_{2-x}\text{Mn}_{1+x}\text{Al}$ films.

Hysteresis loops and thermal dependence of the magnetization were measured in the range 2-300 K using a Quantum Design Magnetic Property Measurement System (MPMS 3).

XMCD measurements were performed on the I06 beamline at Diamond Light Source to determine either the atomic magnetic moments of Fe and Mn (using total electron yield detection) or measure element-selective hysteresis loops (using fluorescence detection). Total electron yield essentially probes surface magnetisation (due to the ~ 5 nm electron escape length), while fluorescence detection probes to a depth of ~ 200 nm and allows accurate measurements in variable magnetic fields.

To determine the magnetic moments, soft X-ray absorption spectra (XAS) near the Fe and Mn $L_{3,2}$ edges were obtained at 1.6 K for parallel (I^+) and antiparallel (I^-) alignment of photon helicity with respect to the applied magnetic field. Magnetic fields in the range ± 6 T were applied to magnetize the sample, at an angle 75° with respect to film normal. The XMCD signal ($I^+ - I^-$) was then analyzed using XMCD sum rules⁵¹⁻⁵³ to extract the overall magnetic moments of Fe and Mn and separate their orbital and spin contributions for two samples of $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ grown in the same deposition run. A correction factor of 1.47 was used to adjust the Mn spin moment in order to remove intermixing complications between the L_3 and L_2 edges⁵⁴.

XRD patterns of the as-deposited $\text{Fe}_{2-x}\text{Mn}_{1+x}\text{Al}$ films (Supplementary Note 1) show only principal reflections of the type $(h+k+l)/2 = 2n$, consistent with the films being isotropic nanocrystals that display the disordered $A2$ Heusler structure and no traces of spurious phases⁵⁵. After heat-treatment, the (111) and (200) superlattice reflections appear with intensities that vary strongly with x , consistent with the creation of chemical order due to the formation of the $B2$ and $L2_1$ phases (Fig. 1a).

For varying Mn content of the heat treated films, we have performed a quantitative analysis of the XRD patterns to determine the degree of $B2$ and $L2_1$ ordering *via* the order parameters S_{B2} and S_{L2_1} ⁵⁶. To minimize experimental uncertainties, we prepared and analyzed three equivalent samples for each value of x . For each sample we measured the peak intensities I_{111} (I_{200}) relative to I_{220} , I_{400} and I_{422} , thus obtaining $3 \times 3 = 9$ independent measurements of S_{L2_1} (S_{B2})⁵⁶ for each value of x . We find that the average of S_{L2_1} over these nine measurements decreases with x , while the average of S_{B2} increases, showing that Mn enrichment favors the $L2_1 \rightarrow B2$ transformation (Fig.1b). Therefore, for increasing Mn content, Fe is more likely to occupy the Fe sites (8c) implying that X-YZ disorder decreases, while Mn and Al are more likely to exchange their sites (4a and 4b respectively) implying that Y-Z disorder increases.

SQUID hysteresis loops measured at $T = 4$ K for the heat-treated $\text{Fe}_{2-x}\text{Mn}_{1+x}\text{Al}$ ($x = -0.25, 0, 0.25$) films (Fig. 2a) show that the coercivity increases linearly with increasing Mn content (from 47 mT for $\text{Fe}_{2.25}\text{Mn}_{0.75}\text{Al}$ to 186 mT for $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$) while the saturation magnetization decreases linearly (from 360 kA m^{-1} for $\text{Fe}_{2.25}\text{Mn}_{0.75}\text{Al}$ to 110 kA m^{-1} for $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$) as previously observed in bulk samples of similar composition⁴³.

After field-cooling to $T = 4$ K, the $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ film shows the exchange-bias effect (Fig. 2b) with exchange-bias field $H_{\text{eb}} = (H_{\text{c1}} - H_{\text{c2}})/2 = 11 \pm 0.2 \text{ mT}$ ($H_{\text{eb}} = 36 \pm 0.5 \text{ mT}$ after field cooling to $T = 2$ K, Supplementary Note 2). The shift of the hysteresis loop is apparent in the second quadrant because of the circumstantial increase in coercivity. After cooling to $T = 4$ K, $H_{\text{eb}} = 4.7 \pm 0.7 \text{ mT}$ for the Fe_2MnAl film and $H_{\text{eb}} = 0 \pm 0.2 \text{ mT}$ for the $\text{Fe}_{2.25}\text{Mn}_{0.75}\text{Al}$ film, such that H_{eb} decreases linearly with decreasing Mn content (inset Fig. 2b).

We have used XMCD to investigate the element-specific magnetic behaviour of these films. For films of all compositions, the saturated XMCD signal of element selective hysteresis loops is ~ 5 times larger for Fe (Fig. 3a) than for Mn (Fig. 3b), showing that Fe provides the dominant contribution to the overall magnetic moment. Moreover, for increasing Mn content, both Fe and Mn moments decrease, in agreement with the decrease of the overall magnetic moment detected by SQUID magnetometry. For increasing Mn content, the Fe XMCD loops show a dramatic decrease of remanent magnetization and low-field susceptibility, accompanied by a progressive increase of high-field susceptibility. These changes are consistent with the hypothesis that part of the XMCD signal increasingly originates from a canted AFM phase. Similarly clear trends with increasing Mn content are not evident in the Mn XMCD loops because of poorer signal to noise ratio.

For the $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ film, analysis of the XMCD data (Fig. 4c&d) using sum rules⁵¹⁻⁵³, yields $0.605 \pm 0.03 \mu_B$ for the magnetic moment of Fe, $0.155 \pm 0.06 \mu_B$ for Mn, and $1.25 \pm 0.08 \mu_B/\text{f.u}$ for the total magnetic moment (we have used 3.4 and 4.5 for the 3d-holes number for Mn and Fe respectively^{57,58}). Table 1 summarizes the m_{spin} , m_{orb} and m_{total} for the $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ film. m_{spin} dominates the total magnetic moment due to orbital hybridization and the orbital moment has been shown to be negligible⁵⁹. The trend is also consistent with previous XMCD reports for Fe_2MnAl ⁶⁰.

Given that both the Fe and the Mn moments are positive, we conclude that ferromagnetic Fe-Mn interactions are predominant. We could not apply XMCD sum rules to the films richer in Fe because their XAS spectra measured in total electron yield did not possess the required high-quality, due to some degree of surface oxidation (Supplementary Note 3). Our $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ film did not show any trace of surface oxidation (even though it is the richest in Mn, which has higher oxygen affinity than Fe) likely because it displays low surface roughness, such that protection from the 2.5 nm-thick Al capping layer is very effective (Supplementary Note 4).

For increasing Mn content, changes in the magnetic properties of our Heusler films can be explained by the formation of an antiferromagnetic phase. This antiferromagnetic phase can only be the $B2$ phase, given that our XRD analysis shows that a partial $L2_1 \rightarrow B2$ phase transformation is the only change to the crystal structure that is induced by increasing Mn content. The $L2_1$ phase of bulk Fe_2MnAl is ferromagnetic⁴³ while the $B2$ phase can be

argued to be antiferromagnetic^{61,62}. Therefore, the properties of our films are understood in terms of a mixed state, where ferromagnetism from the $L2_1$ phase coexists with antiferromagnetism from the $B2$ phase as in bulk Ni_2MnAl ^{61,62}.

For bulk Heusler alloys in the $L2_1$ - $B2$ mixed state, the magnetization curves obtained as a function of temperature after cooling with (FC) and without (ZFC) an applied magnetic field are split^{43,62}. This splitting is incompatible with a collinear homogeneous antiferromagnetic state, and has been attributed to pinning of ferromagnetic moments *via* antiferromagnetic anisotropy^{43,62,63}. This suggestion implies that the $L2_1$ - $B2$ mixed state is heterogeneous, with separated ferromagnetic and antiferromagnetic regions. However, in the absence of direct observations, the microstructure of the mixed $L2_1$ - $B2$ Heusler state has remained so far elusive.

In our nanocrystalline films, we observe split ZFC-FC curves (Supplementary Note 5), consistent with the $L2_1$ - $B2$ mixed state and an heterogeneous microstructure. To check this conclusion directly, we have performed a STEM study with composition analysis (Fig. 5). STEM-HAADF images for increasing Mn content (Fig. 5a-c) show that films are nanocrystalline with an average grain size that increases from 28 ± 2 nm (for $x = -0.25$) to 82 ± 3 nm (for $x = 0.25$). The corresponding elemental maps show that for increasing Mn content the grains become progressively richer in Fe (Fig. 5d-f) and poorer in Mn (Fig. 5g-i), while the intergrain volume becomes richer in Mn and poorer in Fe. Elemental maps for Al (Fig. 5j-l) indicate a behavior similar to Fe. The elemental maps suggest that substituting Mn for Fe drives the nanosegregation of a Mn-rich phase outside the grains, with an Fe-rich phase inside the grains.

For the Fe_2MnAl and $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ films, that show the exchange-bias effect, NMF analysis (Fig. 6a&b) yields two separate Fe-Mn-Al ternary phases, one Fe-rich and a Mn-rich. The compositions of these ternary phases (Table 2) should be taken as qualitative, because they can be affected by local inhomogeneities in EDX artifacts, such as fluorescence peaks and different local absorption of emitted X-rays. While the quantification of larger-area integrated EDX data provides a more accurate estimate of the film composition, NMF evidences the segregation into the two phases and unambiguously show that they are ternary compounds of Fe, Mn and Al. For both the Fe_2MnAl and the $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ films, the spatial maps (loadings) of the Fe-rich and Mn-rich phases show that intragrain volumes are Fe-rich, while intergrain volumes are Mn-rich. For the $\text{Fe}_{2.25}\text{Mn}_{0.75}\text{Al}$ film (data not shown), the Fe-

rich factor did not show clear grains as it was homogeneously distributed over length scales consistent with negligible nanosegregation for this sample.

We now combine the microstructural informations that we obtained by STEM with quantitative SQUID and XMCD magnetometries, to show that the exchange-bias effect originates from the observed nanosegregation process.

For the $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ film, the total magnetic moment deduced from the SQUID data (using the volume of the whole film) is $0.55 \pm 0.01 \mu_{\text{B}}/\text{f.u.}$, i.e. $\sim 44\%$ of the value of $1.25 \pm 0.08 \mu_{\text{B}}/\text{f.u.}$ obtained by XMCD. This discrepancy can be solved by noting that, due to phase segregation, the Fe-rich grains constitute $\sim 45\%$ of the field of view of a $2 \mu\text{m} \times 2 \mu\text{m}$ STEM image (zoomed image shown in Fig. 5i). Using the reduced volume occupied by the Fe-rich phase instead of the whole film, SQUID yields a total magnetic moment of $1.22 \pm 0.06 \mu_{\text{B}}/\text{f.u.}$ in good agreement with XMCD. Therefore, only the Fe-rich phase is ferromagnetic, while the Mn-rich phase is antiferromagnetic.

The Fe-rich grains constitute $\sim 71\%$ of the field of view of a $2 \mu\text{m} \times 2 \mu\text{m}$ STEM image of the Fe_2MnAl film (zoomed image shown in Fig. 5f). Therefore the packing fraction of the Mn-rich (Fe-rich) phase increases (decreases) with Mn content from $\sim 29\%$ (71%) in the Fe_2MnAl film, to $\sim 55\%$ (45%) in the $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ film. This trend mirrors the increase (decrease) of the S_{B2} (S_{L21}) ordering parameter with increasing Mn content (Fig. 1b) which suggests that the Mn-rich segregated phase is the $B2$ phase, while the Fe-rich segregated phase is the $L2_1$ phase. Consistently, XRD shows no sign of other phases, either crystalline (e.g. β -Mn phase⁶⁴) or amorphous (as expected, in view of our magnetic data and heat treatments).

Therefore, our samples present an heterogeneous $L2_1$ - $B2$ mixed state, with ferromagnetic nanograins surrounded by antiferromagnetic regions. This microstructure is similar to core-shell systems where the exchange-bias results from interfacial exchange-coupling between the ferromagnetic core nanoparticles and the surrounding antiferromagnetic matrix¹⁵.

In summary, we have presented the first study of the magnetic and structural properties of Heusler Fe_2MnAl individual thin films. The films of interest display mixed $L2_1$ - $B2$ crystallographic structure (induced by post-deposition heat treatments) and are phase-

separated due to a nanosegregation process which depends on the Mn concentration. This nanosegregation creates a microstructure similar to core/shell systems, and thus establishes an exchange-bias effect that can be tuned by varying the Mn concentration. We show that exchange-bias arises from interfacial exchange-coupling between the Fe-rich ferromagnetic L_{21} phase and the Mn-rich antiferromagnetic $B2$ phase. Our report of exchange-bias in an environmentally friendly nanocomposite film, should inspire the development of single-layer spin valve devices which are sustainable.

All data measured at $T = 1.6$ K in a 6 T applied magnetic field.

Figure 5. Nanosegregation in $\text{Fe}_{2-x}\text{Mn}_{1+x}\text{Al}$ films with exchange-bias. For (a, b, c, d) View Article Online
DOI: 10.1039/C9NA00689C

$\text{Fe}_{2.25}\text{Mn}_{0.75}\text{Al}$ (e, f, g, h) Fe_2MnAl and (i, j, k, l) $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ we present HAADF images (a, e, i) and elemental quantitative EDX maps for (b, f, j) Fe, (c, g, k) Mn and (d, h, l) Al.

Figure 6. Compositions of the segregated phases in Fe_2MnAl and $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ films by NMF analysis of the EDX spectra. For the (a) Fe-rich and (b) Mn-rich NMF factors and corresponding loadings (spatial maps) are shown for (c,d) Fe_2MnAl and (e,f) $\text{Fe}_{1.75}\text{Mn}_{1.25}\text{Al}$ films. The colour scale intensity indicates the weight of the factor for a given pixel.
